A. INTRODUCTION

The present report summarizes the results of subsoil investigation operations conducted in connection with the proposed Whitesand Creek bridge at mile 459.6 on the Mackenzie Highway.

This bridge site investigation was undertaken as part of the geotechnical investigation from mile 450 to 550 on the Mackenzie Highway for the Department of Public Works, Government of Canada.

It was the intention of the present investigation to determine the vertical sub-soil material sequence, physical and structural properties, permafrost conditions and ground water conditions which would be expected to influence the stability of the valley slopes and the design and construction of the bridge foundation.

The included conclusions and recommendations have been based upon exploratory and sample acquisition operations conducted at a total of 9 positions along the proposed bridge center line in the river

channel and slopes of the bridge approaches.

In the formulation of conclusions and recommendations, the consistency and composition of the subsoil material between and in the proximity to the individual test boring positions has been assumed but hot verified.

B. FIELD AND LABORATORY INVESTIGATION

A total of 9 test holes have been drilled within one mile of the bridge structure. In addition to the 9 centerline testhole logs, 9 borrow test hole logs in the vicinity of the bridge site have been included in the Appendix. Test holes along the centerline were drilled to depths varying from 11 to 90 feet below the existing site grades. Borrow test holes were generally advanced to the 15 foot level.

Test borings were drilled December 6, 8 and 12, 1972, and January 9 and 12, 1973, by Kenting Big Indian Drilling of Calgary, utilizing a Meyhew 1000 and Heli drill. Air recovery methods were generally employed except where severe caving was encountered at bridge crossings, water and mud drilling methods were utilized. The locations of the individual test borings were selected and located by Underwood McLellan & Associates Limited. The approximate test boring locations are graphically illustrated on the accompanying Mosaic and Test Hole Location Plan.

З.

All variations of soil, permafrost and groundwater conditions encountered during the test hole boring operations were noted and representative samples of the existing subsoils were taken. The majority of the samples were disturbed having been obtained by air recovery methods. Sampling was also undertaken with 2" and 3" O.D., split spoon sampling tubes and 3" O.D. thin walled Shelby tubes. In the laboratory materials obtained from the drilling operations were subjected to standard laboratory classification procedures including particle size distribution and Atterberg index property determination. Moisture contents were obtained for all samples returned to the laboratory. Wherever a sufficient length of intact sample was retained in the penetrometer tube, both wet and dry densities were obtained.

Permafrost samples were classified according to NRC technical memorandum No. 79 "Guide to the field description of permafrost." The excess ice content

in permafrost samples was determined by visual inspection and by measured thicknesses of ice lenses. The excess ice content was obtained by division of the ice thickness by the total sample thickness.

All soil samples were classified according to the Unified Soil Classification system.

All results of laboratory and field tests are summarized in the Appendix on the test hole logs.

Test holes have been designated by mileage, type and number. Examples include 459C 80B, 459S 132A and 459B 159B. The letter symbols and numbers indicate

459 - indicates mileage

B, C, and S - between mileage and test hole number indicates borrow, centerline or

structure test holes, respectively. 80, 132 and 159 - indicate test hole numbers. A, and B - after test hole numbers indicate drilling

performed by Meyhew 1000 or Heli drill, respectively.

Test holes should be designated by a number

followed by A or B.

C. SITE AND SUBSOIL CONDITIONS

The Whitesand bridge site is located at mile 459.6 (chainage 880 + 00) on the Mackenzie Highway in the Northwest Territories. The Whitesand river flows into the Mackenzie River from the east having a drainage basin which extends to the Franklin mountains. This stream has a typical sand-gravel bed which is presently in a state of depositing floodplain sediments at the entrance to the Mackenzie River.

The Whitesand stream bed elevation is 280 (DPW datum) with the estimated high water mark at elevation 306 as a result of ice jams along the Mackenzie River. The main valley of the Whitesand Creek is approximately 400 feet wide, and 50 feet deep. The main stream flow in recent years has been against the north bank in a trench approximately 100 feet wide and 15 feet deep.

Two test holes 124A (879 + 70) and 132A (881 + 70) were drilled at the bottom of the main valley to depths of 40 and 90 feet, respectively. Test hole 124A disclosed alternating layers of sand and gravel to the termination of the hole. These granular materials exhibited very low moisture contents and the water table was indicated at 22 feet below existing grades which was approximately coincident with the stream water level.

Test hole 132A which was drilled to a depth of 90 feet disclosed alternating sand and gravel layers to a depth of approximately 70 feet where a sandstone and shale bedrock was confirmed. The bedrock in the general area of the investigation is believed to consist of sedimentary deposits of interbedded shales siltstones and sandstones which were deposited during the Cretaceous Geologic age. Test hole 124A did not disclose any permafrost but test hole 132A indicated permafrost to a depth of approximately 30 feet where the water table was encountered. Below the water table, the soil would

be classified as semi-frozen.

Although the mud and water circulation method was utilized, sloughing was extensive and "undisturbed" samples could not be retrieved.

Test holes drilled along the valley walls and near the uplands within approximately $\frac{1}{2}$ mile south and north of the proposed bridge site disclosed granular sand and gravel deposits which were previously deposited by the Whitesand stream when it flowed at higher elevations. It may also be concluded from the test holes drilled that the stream banks and upland consist primarily of permafrost. The majority of the granular materials exhibit very low moisture contents although these materials are frozen.

The gravel samples which were obtained during drilling operations indicated approximately 50% material coarser than the # 10 sieve, but these samples which were subjected to crushing during drilling would exhibit a true gravel size content

higher than recorded.

Exception to the dry granular materials was indicated in test hole 123A (885 + 00) which has a surface deposit of 16 feet of high moisture content silt and clay with excess ice contents of approximately 5%. The dry density of the silt clay varied from 88.7 to 92 lb/cu.ft. The materials below the 16 foot level in test hole 123A consisted of dry sand with some boulders and was further underlain by a firm clay till of stiff consistency.

A Soil Profile of the bridge valley site is included in the Appendix on Plate 2.

D. CONCLUSIONS AND RECOMMENDATIONS

On the basis of the present investigations we wish to offer the following generalized conclusions and recommendations relative to the design and construction of the proposed Whitesand Creek bridge foundations and approaches.

1. Pier and abutment foundation.

A footing foundation for the abutments and piers will be founded in the gravel and sand deposits which are described in the previous section. These materials which were stream deposited have not been subjected to preconsolidation and significant settlements would result under foundation loadings. In addition, considerable difficulty would be experienced in performing excavations for piers in the saturated granular soil. Consequently, a driven pile foundation system is recommended for all structures.

The pile types generally available would include timber, precast concrete, steel H-piles and pipe piles. The timber piles are not recommended as a result of their low capacity and

possible damage when driving through gravel strata. The pre-cast concrete piles are also not recommended primarily due to the difficulty in establishing ultimate pile lengths and unless the lengths can be pre-determined considerable difficulty in splicing results.

Steel H-piles or pipe piles are, therefore, recommended for consideration primarily based on high driving strength, high load capacity and relative ease in splicing. The granular strata at this site will provide adequate lateral support such that instability in the form of buckling of the piling will not be a problem.

It is recommended that all piles be driven to "refusal". "Refusal" will depend upon the energy rating of the hammer but is commonly 15,000 ft. lb. As an initial guide, piles should be driven to blow counts of 180 blows/ft. or 15 blows/inch. The pile capacity is largely

a function of the amount of energy expended in installing the pile and not just of the recorded resistances. The pile which is driven to a sustained resistance will perform better than one which is terminated the instant a given resistance is attained. Of course, the pile must not be driven until damage occurs and whenever resistance increases greatly, the driving should be terminated.

At the Whitesand Creek site, it is anticipated that steel pipe or H-piles for piers will be approximately 60 feet long based on data summarized on test hole log 132A where bedrock was encountered at elevation 220. The pier foundations will be nearer the stream channel than test hole 132A and the "rotten" nature of the permafrost will likely be more developed. Difficulty exists in establishing the insitu density and therefore, predicting the "refusal" depth in gravel strata. Steel piles driven to refusal can be expected to attain allowable load capacities in the range of

80 tons depending upon the steel section area. "False" refusal may occur whenever extremely large boulders cannot be penetrated during driving. Such boulders were encountered at the 16 foot level in test hole 132A.

Although refusal may be attained while driving, fundamental refusal bearing capacity may not exist below the pile tip. Load tests would be necessary to establish allowable pile loads if this situation is recognized. In order to attain penetration of the steel piles around large boulders, it may be necessary to utilize vibration techniques. Alternatively, large diameter open steel pipe may be utilized to penetrate boulder strata by crushing the boulders with churn-drill methods within the pipe pile.

Whenever conventional driving techniques are employed, the capacity of a pile should be established in the field by several pile-driving tests. The ultimate capacity would be calculated

on the basis of a dynamic pile-driving formulae such as the Hiley, Danish or Weisbach. It is recommended that the Engineering News formula not be utilized as a result of its extreme variation in factor of safety.

The south abutment location is proposed in the large fill section at station 881 + 40. Wherever the embankment consists of compacted granular fill as recommended in section D3, the abutment may be placed on a spread footing utilizing 4000 pcf allowable bearing stress. If inferior materials or compaction techniques are utilized in the embankment, the foundation must consist of driven piles into the granular subsoils below. Piles driven through fills subject to settlement must be designed to carry negative skin friction.

At the north abutment, station 883 + 90, a change from fill to cut occurs at the proposed location. The soil strata consists of clayey silt and clay permafrost at this elevation and would not allow satisfactory long-term abutment foundation performance. Piles driven to refusal in the glacial till at elevation 308 should be utilized but steam-jetting of the surface materials will likely be necessary to achieve penetration.

It is further recommended that static load tests be performed to establish more accurately the bearing capacity of a typical steel pile and the applicability of dynamic pile formulae. Data obtained from load tests on piles driven into deep granular deposits will be of assistance in designing piles throughout the Mackenzie Highway System.

The lateral resistance of piles can be established by recently developed methods based on the beam on elastic foundation method but the simple and more conventional approach is based on calculation of the Rankine passive earth pressure against the pile. Using Rankine theory the ultimate passive resistance force/ft² of pile can be obtained by $P = \frac{1}{2} \chi_{b} K_{p} H^{2}$. The submerged unit weight of the granular material may be taken as 60 pcf and the passive pressure coefficient K_p as 3.0. In order to establish the allowable lateral load a factor of safety of 2.5 should be applied to the above ultimate load. Generally, in cohesionless soils the lateral load tends to exceed the passive resistance and the above simplified approach is on the conservative side.

2. Lateral Abutment Loads

The magnitude of the pressure applied to the abutment will depend upon the characteristics of the backfill chosen for the approach fill and upon the movements that the wall undergoes during and subsequent to fill compaction.

It is recommended that granular backfill from the river terraces or borrow pits be utilized for the abutment approach embankments which will be in the order of 30 feet high.

The most common procedures for analysis of the earth pressures against gravity retaining walls include the Rankine and Coulomb methods.

Generally, it is assumed that the wall rotates sufficiently to allow mobilization of the backfill shear strength which reduces the pressure to the active case, the lowest pressure that can be realized. This assumption applies reasonably accurately when the backfill consists of uncompacted granular material but pressures greater than the active occur wherever compaction of the backfill is undertaken. While the total yield at different elevations on the abutment may be adequate for mobilization of the full backfill strength, a gradual build-up of the backfill also results in a gradual yielding of the wall. Therefore, by the time the backfill is complete only a fraction of the total yield of the wall has become effective in decreasing the earth pressure. At the present time it is accepted that the actual earth pressure magnitude will exceed the active case and may approach the earth pressure at rest. Pressures greater than the at-rest case may occur if

heavy equipment is utilized near the concrete abutment.

If the Coulomb approach is utilized, the angle of wall friction between concrete and coarse sand and gravel would be 20 degrees. The angle of internal friction for compacted granular material would be 38 degrees and the dry density may be taken as 115 pcf. For a simple verticle retaining wall abutment with horizontal backfill the Coulomb active coefficient would be .24 and the at-rest coefficient based on $K_0 = 1 - \sin \phi$ would The Rankine procedure which disregards be .38. the wall friction would also result in an active coefficient of .24. Whenever the wall or backfill are inclined or a surcharge exists, the Coulomb procedure will result in a lower active pressure which will be more exact than the conservative Rankine method. The pressure distribution behind a gravity retaining wall has been shown to be non-

triangular, but as a first approximation and for simplicity, the triangular pressure diagram is recommended. It is also recommended that whenever backfill is compacted in lifts by vibratory compactors the at-rest coefficient may be utilized for calculation of the ultimate earth pressure.

A driven pile foundation has been previously recommended for the abutments which will provide significant lateral resistance but it is further recommended that some batter piles be utilized to ensure adequate lateral support against earth pressures.

Positive drainage including horizontal perforated tile and weep holes should be provided to prevent development of hydrostatic pressure against the wall. In addition, free drainage of water will prevent the development of frost heaving pressures against the walls.

3. Bridge Approach Grades and Borrow Material

Major cuts are proposed at the north and south banks of the proposed bridge site. The cut on the south bank at station 872 + 00 will be approximately 35 feet in height and will extend approximately 1,000 feet. These cuts will be performed in dry frozen sand and gravel with no excess ice. It is anticipated that the stability of this cut slope will not be a problem and a slope of 2:1 is recommended, although a flatter slope may be employed to increase available fill material.

The cut on the north bank at station 886 + 00 will be undertaken in primarily dry gravel and sandy silt with moisture contents less than 6%. In the lower portion of the cut section at station 885 + 00, the cut of 10 feet will be primarily in silt and silty clays with moisture contents in the order of 25% and excess ice contents of 5%. At this

section cut slopes of 2:1 are recommended.

Some sloughing of the 10 foot cut can be expected after excavation during thermal readjustment. It is recommended that consideration be given to raising the grade line approximately 12 feet near the north abutment to eliminate cutting in the surface silt permafrost. Some thaw settlement can be expected as the section would be composed of a four foot fill.

Fills of 3 to 5 feet have been proposed north and south of the major cuts which were described in the above paragraph. These fill heights are considered adequate at stations 894 + 00 and 864 + 00 as the subgrade consists of dry granular soil which is not expected to undergo significant thaw settlements, but in the area of test hole 80B at station 855 + 00 approximately 10 feet of fine sandy silt is present which exhibits moisture contents of 40%; dry density near 70 pcf., and contains random ice. It is expected that thaw settlements in the order of 1 to 2 feet will occur.

Therefore, it is recommended that the fill depth in this area be increased to approximately 8 feet if granular materials are utilized.

The approach fills to the bridge will be approximately 30 feet high and it is recommended that because of an adequate granular material supply, these materials be utilized in all fills near the bridge approaches and be compacted to 95% of Standard Proctor utilizing vibratory compaction. Although construction may be performed during the winter, the dry nature of the granular materials will allow adequate compaction. Compaction of these deep approach fills is mandatory to ensure slope stability and all fill slopes should be constructed at slopes of 2:1.

In addition to common excavation which will be obtained from valley cut sections, granular

borrow material may be found adjacent to the centreline at station 871 + 00 and 891 + 00. The borrow pit investigated at station 831 + 00 consists of silty clay with moisture contents in the range of 40% and is not considered suitable for roadway embankment fill. Test hole logs for the borrow material are included in the Appendix.

APPENDIX

EXPLANATION OF FIELD & LABORATORY TEST DATA

The field and laboratory test results as shown for a particular test boring by the Test Hole Log Data Sheet are briefly described below:-

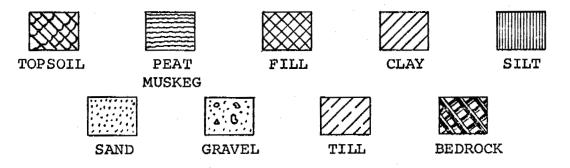

NATURAL MOISTURE CONDITIONS & ATTERBERG LIMITS

The relation between the natural moisture content and depth is significant in determining the subsurface moisture conditions. The Atterberg Limits should be compared to the Natural Moisture Content of the subsurface soil as well as plotted on the Plasticity Chart.

SOIL PROFILE & DESCRIPTION

Each soil strata is classified and described noting any special conditions. The unified classification system is used, and the soil profile refers to the existing ground elevation. When available the ground elevation is shown.

The soil symbols used are briefly shown below but are indicated in more detail in the Soil Classification Chart.

TESTS ON SOIL SAMPLES

Laboratory and field tests are identified by the following symbols:

- QU unconfined compressive strength usually expressed in tons per square foot. This value is used in determining the allowable bearing capacity of the soil.
- Jd dry unit weight expressed in pounds per cubic foot. This value indicates the density or consistency of the in-situ soil.

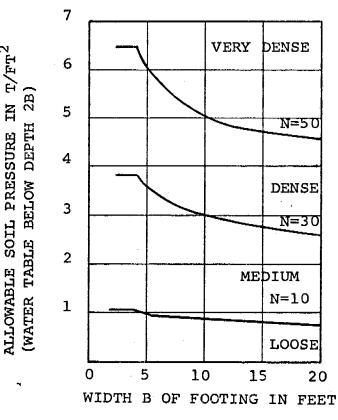

- 1 -

- C Consolidation test. These test results are separately enclosed and provide information on the consolidation or settlement properties of the soil strata.
- M.A. grain size analysis. These test results are separately enclosed and indicate the gradation properties of the material tested.
- SO₄ water soluble sulphate content is conducted primarily to determine whether sulphate resistant cement is required for the foundation structure.
- N standard penetration field test. This test is conducted in the field to determine the in-situ consistency of a soil strata. The "N" value recorded is the number of blows from a 140 lb. hammer dropped 30 inches (free fall) which are required to drive a 2" O.D. Raymond type sampler 12 inches into the soil.

The resistance and unconfined compressive strength of a cohesive soil can be related to its consistency as follows:-

N - BLOWS/Ft.	$QU - T/Ft.^2$	CONSISTENCY
2	0.25	very soft
2-4	0.25-0.50	soft
4-8	0.50-1.00	medium or firm
8-15 .	1.00-2.00	stiff
15-30	2.00-4.00	very stiff
30	4.00	hard

The resistance of a non-cohesive soil (sand) can be related to its consistency as follows:-

- 2 ·

SAMPLE CONDITION AND TYPE

The depth and condition of samples are indicated by the following symbols:

SAMPLE TYPES

T - 3" O.D. Shelby tube sample
P - penetration tube sample
C - rock core sample

PERCENTAGE WATER SOLUBLE SULPHATE CONCENTRATION

0 0.1 0.2 0.3 0.4 0.5 0.6 0.7%

Negli- gible	Posi- tive	Considerable	Severe
	RELATIVE	DEGREE OF SULPHATE AT	TACK

Negligible - Normal Portland Cement may be used.

<u>Positive</u> - Normal Portland Cement may be used, provided the strength of the concrete is increased up to 500 psi higher than the compressive strength which would normally be used.

<u>Considerable</u> - Type V cement must be used and the concrete compressive strength should be increased to 500

- 3 -

psi higher than the compressive strength which would normally be used.

<u>Severe</u> - Type V cement must be used and the concrete compressive strength should be increased from 500 to 1000 psi higher than the compressive strength which would normally be used.

GROUND WATER TABLE

The water table is indicated by the level of standing water in a test boring after equilibrium has been reached. This is generally taken 24 hours after the drilling operation. The water table is usually an inclined surface that is dynamic in nature with its highest level late in the winter or early spring gradually falling throughout the summer.

UNDERWOOD MILELLAN & ASSOCIATES LIMITED

NATIONAL RESEARCH COUNCIL PERMAFROST CLASSIFICATION SYSTEM

Permafrost ground ice occurs in three basic conditions including non-visible, visible (less than one inch in thickness) and clear ice.

A. <u>Non-visible</u> - N

 N_{f} - poorly bonded or friable frozen soil N_{bn} - well bonded soil, no excess ice N_{be} - well bonded soil, excess ice

B. <u>Visible</u> - V (less than 1" thick)

V_x - individual ice crystals or inclusions

V_c - ice coatings on particles

V_r - random or irregularly oriented ice formations

V_s - stratified or oriented ice formations

C. <u>Visible Ice</u> - (greater than 1" thick)

Ice - ice with soil inclusions

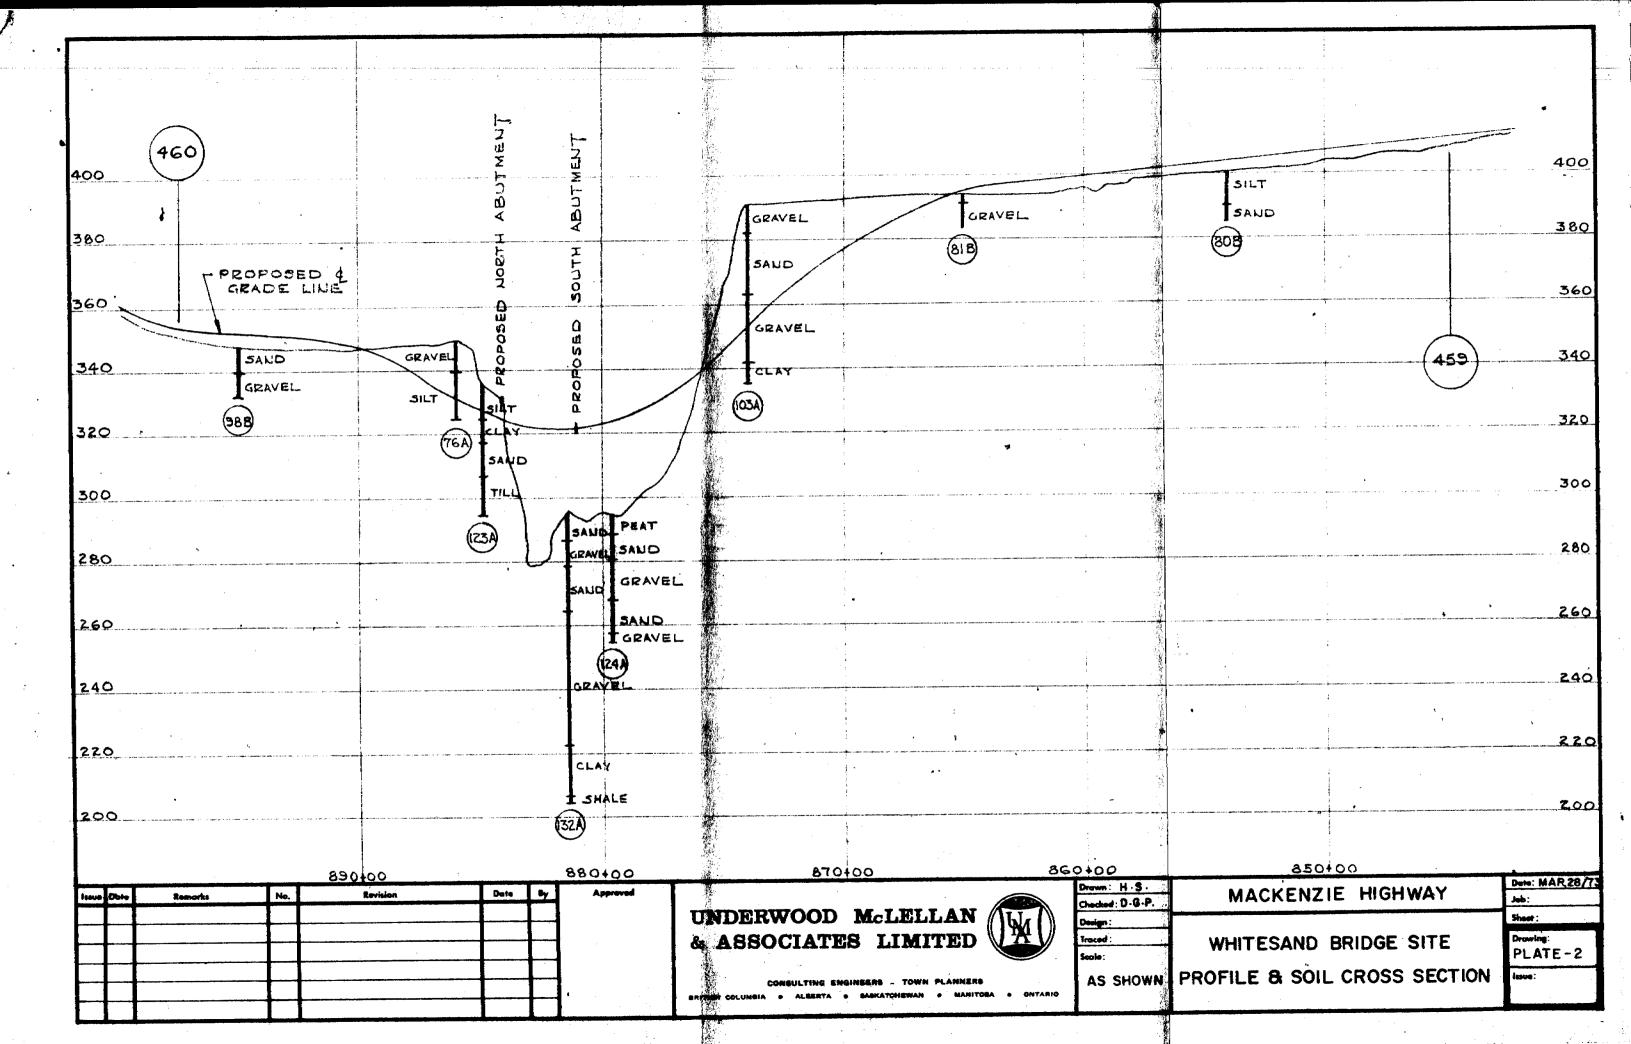

Ice + Soil - ice without soil inclusions.

A more complete description of this system is included in NRC publication TM 79.
