I Preliminary

The initial highway alignment in the area of the Martin River was established in 1972. Geotechnical exploration along the route was carried out that same year and included foundation borings for a bridge structure at the Martin River and investigation of the bridge approaches. These initial borings identified an extensive permafrost condition in the north-west valley bank which is immediately adjacent to the stream channel. Materials in the slope were ice-rich, thaw-unstable clays that were particularly sensitive to surface disturbance, and which presented a major design and construction problem. In February 1973 an evaluation report was prepared comparing costs and other factors for two different levels of crossing along the original alignment, as well as two projected alternate alignments. It was concluded that an alternate routing some 3500 feet downstream from the original alignment was most suitable and has been selected as the crossing site.

- 1 -

The proposed crossing route and the original alignment are shown on the site plan in Appendix A. Also shown thereon is a temporary Bailey Bridge located some 2500' upstream from the proposed crossing. The temporary bridge is founded upon timber cribs filled with heavy granular deposits from the river bed. This Bailey Bridge will be relocated to the revised crossing site and reconstructed roughly 150' downstream from the centerline and the proposed location of the permanent structure.

Detailed log sheets for four (4) foundation borings at the original crossing site are included in Appendix B, along with log sheets for two (2) holes drilled at the present site.

II Crossing Site

The proposed crossing site is located at Mile 306.7 on the Mackenzie Highway. Surficial geology in the area consists of thin (30-60') ablation moraine deposits, on basal glacial till, over shale bedrock. The Martin River has incised a relatively narrow, shallow valley into the ablation moraine materials (primarily sands and silts with some clay), and in the area of the crossing is currently flowing near the ablation morainebasal till interface. The surface of the till has a relatively high granular content and the stream bed is paved with boulders that are probably products of erosion into this stratum.

At the bridge site the river is presently adjacent to the valley slope on the east and the approach to the bridge from that side will be on ablation moraine deposits. On the opposite side is a narrow, valley floor some 500 feet in width where the subsoil consists of relatively shallow

.... 3

- 2 -

(10-15') flood plain deposits - sands, silts, clays and some gravels, over glacial till.

With reference to the site plan in Appendix A, the crossing site is located roughly 500 feet downstream from an oxbow cutoff. Meanders are currently forming in the area of the crossing as a result of the cutoff, and a hydrology consultant has recommended that the east bank be protected against lateral scour at the bridge, and the west bank be protected about 150 feet upstream from the bridge. In addition, the river is presently encroaching on the upper end of the oxbow lake some 2500 feet upstream of the proposed bridge site, and, as the oxbow lake is roughly 7 feet lower than the river channel at this point, the river will eventually break through to the old, cutoff, channel. A possible dyking area some 500 feet upstream of the proposed bridge is shown on the site plan, to direct the flow when this event occurs.

III Subsoil Conditions At Bridge Structure

The two boreholes and the approximate subsoil stratigraphy at the crossing are shown on Drawing A-1 in Appendix A. Hole #5 on the east side of the river was drilled with a rotary rig in February 1975; hole #6 on the west side was drilled with a

.... 4

- 3 -

power auger in March, 1976. Permafrost was reported on the east side but appeared to terminate near a depth of 20 feet in hole #5 (Note - several auger holes were attempted on the east side in March '76 but the equipment was unable to penetrate a frozen granular layer near a depth of 10 feet).

The upper limit of the glacial till is shown on Drawing A-1 near elevation 442 or roughly 6 feet below the stream-bed. Deposits above the till to stream-bed have a significant heavy granular content (gravel, cobbles and boulders), and may be reworked till materials. Maximum penetration into the till was roughly 15 feet. The till is very stiff or dense and auger advance was very difficult near the bottom of hole #6 (West side).

The four boreholes at the original crossing site (3500' upstream) encountered similar subsoil stratigraphy, with shale below the till at an elevation of roughly 435-440 (20-25' below stream-bed). Shale was not reported in either drill hole at the revised crossing, however it is anticipated near elevation 425. It is tentatively planned to drill two additional holes at the revised crossing site to confirm the depth to shale when a rotary rig becomes available in the area, probably in late summer of 1976.

.... 5

- 4 -

IV Foundation Support of Bridge Structure

There are no design details for the proposed permanent bridge, however a single span structure in the order of 130-150 feet in total length is anticipated. A driven pile foundation system is recommended for the abutments.

The glacial till and/or the underlying shale will form the bearing strata for the foundation elements. Steel H-piles are recommended for use primarily because of their high driving strength, high load capacity and relative ease in splicing. The glacial till at this site will provide adequate lateral support such that instability in the form of pile buckling will not be a problem.

Hard driving is anticipated both in the heavy granular zone above the glacial till, and in the glacial till itself. A relatively heavy section-10BP @ 57 lbs./ft.-is recommended. It is anticipated that pile penetration through the granular zone on the east side of the channel will be practically impossible due to the presence of permafrost, hence it is recommended that lead holes be prebored for the piles to the lower limit of the permafrost on this side and the piles driven into the till at the base of the holes. The lead holes should be 14" in diameter assuming a 10" H-pile section. Following pile installation, the cavity around each pile should be filled with free running sand.

6

- 5 -

The subsoil stratigraphy at this site will permit the use of either lightly loaded piles, designed on the basis of shaft friction in the glacial till, or heavily loaded piles, designed for the full structural strength of the pile section acting as a column, and driven to refusal, probably into the shale below the till. "Refusal" will depend upon the energy rating of the drive hammer, but assuming an energy in the order of 15,000 ft. lbs., piles should be driven to blow counts in the order of 15 blows per inch. To ensure that refusal has been reached, driving should be continued for at least 100 blows after the refusal requirement is first recorded. It is anticipated that final refusal will occur near elevation 415-420 or roughly 30-35 feet below stream-bed elevation, however this estimate could be revised pending confirmation of the depth to shale.

Lightly loaded piles may be designed on the basis of an average allowable shaft friction of 500 psf. in unfrozen subsoil (i.e. below a depth of roughly 20 feet from existing grade on the east), with end-bearing ignored.

The allowable lateral load for piles at this site may be assumed at 5 kips per pile for a lateral movement in the order of 1/4 to 1/2 inch.

-

6

There is an abundance of fine dune sand in the Martin River area and it is assumed the backfill against the abutments will be compacted sand. For a simple vertical retaining wall abutment, the earth pressure may be calculated by assuming the backfill to be a fluid with a density of 60 lbs./ cu. ft.

Fill heights immediately adjacent to the abutments will be in the order of 15-20'. Unit loadings imposed on the subsoil from the fills will be relatively small and, as consolidation will only take place in the strata above the glacial till, overall embankment settlements should be minor.
